Curry, the rate of rise during the last 4000 yrs, has been slower, probably of the order of 0.3 to 0.8 cm/yr. Such a slow rate would probably lead to optimum growth of corals and perhaps for this reason some parts of the bank, for example, the pinnacle has reached fairly high.

Since the bank was discovered for the first time by the Research Vessel Gaveshani, it is named as Gaveshani Bank.

The authors thank Dr C. S. G. Pillai for his help in identifying the corals.

Primary Productivity of the Bay of Bengal During March-April 1975

K. Radhakrishna
National Institute of Oceanography
Donategorical 403004, Goa

Received 6 October 1977; revised received 28 January 1978

Primary productivity has been measured at 12 stations in the Bay of Bengal and 2 stations in the south-eastern Arabian Sea, during March-April 1975. Data on phytoplankton and zooplankton standing stocks and inorganic phosphate and nitrate are presented and the correlations between these parameters and productivity discussed. Primary productivity in the Bay of Bengal is maximum at the surface as compared to subsurface waters. Daily productivity varies from 1.56 to 110.26 mg C at the surface and from 0.063 to 0.25 g C in the euphotic column.

ATTENTION ON primary productivity of the Bay of Bengal is limited to few areas. As a part of the oceanographic studies in the Bay of Bengal conducted during March-April 1975 on board INS Darshak, primary productivity measurements were made at 12 stations in the Bay of Bengal and 2 stations in the Arabian Sea. These results are discussed in the present paper.

The samples were collected from predetermined stations after measuring the light attenuation with a submarine photometer. Productivity was measured by the radiocarbon technique after making due correction for dark uptake, under simulated in situ conditions for 24 hr. Radioactivity was counted on a liquid scintillation system. Nutrients were estimated by standard methods. Zooplankton was collected by standard IOSN tows (0-200 m).

Details of station locations and depth, and sampling depths and dates along with primary productivity and related parameters are given in Table 1.

One interesting feature observed in the present study is that at all the Bay stations, productivity at the surface was maximum as compared to other depths sampled in the euphotic zone. This vindicates the view that in the Bay of Bengal, the light intensity at the surface is optimum and is not too high to inhibit photosynthesis as is generally the case in tropical latitudes. This situation is probably due to the relatively heavy cloud cover over the Bay most of the year.

Information regarding the quantitative distribution of phytoplankton in the offshore regions of the Bay of Bengal is very little. A preliminary attempt is made to quantify the phytoplankton standing crop and correlate it with primary productivity and nutrients.

In general, the phytoplankton were relatively high in the oceanic stations both at the surface and in the column although the primary production was low in comparison. On the other hand, in the Sandheads (station 194), the unusually high phytoplankton standing crop of $40 \times 10^6 m^2$ at the surface was associated with high primary productivity. At the offshore stations, cell counts at the surface varied from $10-27 \times 10^6 m^2$ (av. $15.6 \times 10^6 m^2$) and the integrated counts in the column from 300-537.7 $10^6 m^2$ (av. $435.5 \times 10^6 m^2$). The standing crop values for the various stations are given in Table 1.

Diatoms dominated the samples; dinoflagellates were relatively low. Among the diatoms, Bacterium, Rhizosolenia, Chaetoceros and Coscinodiscus were the most frequent and were encountered throughout the area.

Correlations between primary productivity and other variables like phytoplankton, zooplankton and inorganic nutrients are presented in Table 2. Correlation coefficients and their levels of significance are given in order to bring out the inter-relationships of the parameters involved. The correlation between productivity and phytoplankton was not significant at the surface; the coefficient value was 0.52. However, the correlation coefficient between column productivity and column phytoplankton count was -0.58, significant at 10% level.

The inorganic phosphate concentration at the surface in the oceanic region of the Bay of Bengal...
SHORT COMMUNICATIONS

is about 0.2 µg at/litre. The Anton Bruun average was 0.06 and the Galathea average was 0.12 µg at/litre. Low phosphate concentration is generally associated with warm and high saline waters. In the present study, however, phosphate concentrations at the surface were high (0.53-1.97 µg at/litre; av. 1.14 µg at/litre) notwithstanding the prevailing high temperature and salinity (29.0°C and 34.0%). Since these stations were oceanic, the upwelling prevailing along the east coast of India during that season could not have influenced such offshore waters and resulted in such high phosphate concentrations in surface waters. The integral mean concentration (IMC) of the phosphate in the euphotic column was also high (0.77-3.34 µg at/litre; av. 1.55 µg at/litre).

Although the phosphate concentrations were relatively high both at the surface and in the euphotic zone, the productivity was low. For example, at station 204, the surface phosphate value was 1.44 µg at/litre and the surface productivity was the lowest recorded in this study (1.56 mgC/m²). Likewise, IMC of phosphate at this station was 3.34 µg at/litre (the highest recorded) and column productivity — 0.063 gC/m², the lowest recorded (Table 1). The correlation coefficient between productivity and phosphate concentration at the surface was —0.58, significant at 10% level and in the column was —0.49, not significant (Table 2).

Correlation between phytoplankton and phosphate was also not significant either at the surface or in the column.

The inorganic nitrate concentration at the surface in the offshore waters of Bay of Bengal varies from 0.1 to 2.0 (µg at/litre). The average value for the Anton Bruun stations was 0.39 (µg at/litre). But in the present study, the nitrate concentration was high (av. 1.56 (µg at/litre at the surface and IMC of 4.37 (µg at/litre for the column). As in the case of phosphate, at station 204, nitrate was very high at the surface and in the column, IMC of 16.63 (µg at/litre being the highest recorded. Correlations between productivity and nitrate and between phytoplankton and nitrate were not significant. However, the correlation between phosphate and nitrate was significant.

An attempt is made to correlate primary productivity with zooplankton standing crop. Zooplankton biomass in the Bay was poor varying from 0.4 to 2.2 ml/m² (av. 1.76 ml/m²) while at the 2 stations (207 and 209) in the Arabian Sea, the average was 4 ml/m². The Anton Bruun average biomass value was 14 ml/m² for the same season over an extensive area of the Bay. According to the IOBC Atlas, the average for day collections over a year in the Bay is <10 ml. The correlation between zooplankton biomass and other parameters was poor.

In general, primary productivity in the offshore waters of the Bay of Bengal is low. Beyond the continental shelf the Galathea measurements averaged 0.22 and those of Anton Bruun 0.13 (gC/m²) day. Kabanova reviewing the literature on primary productivity in the northern Indian Ocean summarized the various measurements and concluded that the column productivity varied from
0.1 to 0.5 gC/m² while the surface productivity from 100-250 mgC/m²; her data were limited to the winter months only. Nair⁴ calculated the production rate for offshore waters of the Bay as 0.19 gC/m²/day. The present measurements give a comparable average of 0.16 gC/m²/day.

Primary production in the Bay of Bengal is relatively low as compared to the Arabian Sea. This can be attributed to (i) topographical feature like the narrow continental shelf, (ii) meteorological feature like the heavy cloud cover and (iii) certain oceanographic features. The Bay of Bengal, as a whole, is more or less an estuarine sea with an average salinity of 30-34%o. A number of major rivers open into the Bay both from east and west sides, bringing in huge quantities of inorganic and organic material which lower the transparency of the waters to a considerable extent, thus limiting photosynthesis. Upwelling in the Bay is less intense and limited compared to the Arabian Sea. The heavy river discharge offsets the offshore transport of surface waters caused by winds and thus damps upwelling. The other oceanographic mixing processes (vertical advection, diffusion etc.) that transfer the subsurface nutrients to the euphotic zone are also less intense in the Bay as there is a greater degree of stratification and stability due to the river discharge and concomitant lowering of salinity in the surface waters.

The author is grateful to Dr S. Z. Qasim for his valued criticism, to Dr R. Sen Gupta for making available the nutrient data and to Capt. K. L. Chopra, officers and crew of INS Darshak for shipboard facilities.

Biodegradation of Organic Matter in Sea Water

A. Rajendran
National Institute of Oceanography
Dona Paula 403004, Goa

Received 1 December 1977

Biodegradation of 3 different biological materials (Trichodesmium erythraeum, Lucifer and mixed plankton) was studied to estimate their rate and extent of decomposition in surface sea water under controlled laboratory conditions. Rate of decomposition during the first 20 days was approximated by the 1st order Kinetics. Rate constants for the degradation suggested that there were 3 stages in the microbial decomposition and that 2 labile organic fractions and a refractory organic fraction could be identified. Approximately, 15-20% of the initial dissolved organic matter (DOM; fraction F₁) was oxidized. The other labile fraction F₂ was about 30-45% of the total DOM. The refractory portion was about 40%, and it was resistant to biological oxidation. Rate constant for F₁ of T. erythraeum was 0.0331 day⁻¹ and of Lucifer was 0.0723 day⁻¹ and for mixed plankton, it was 0.1188 day⁻¹.

Primary sources of energy of the coastal aquatic ecosystem are available at the producer-decomposer level. Number of dynamic and interacting environmental parameters influence this basic trophic level and control the development and optimization of energy flow. Higher components of the system such as predators, influence production rates within the system with their own variable populations and production dynamics.

Autotrophic productivity and related heterotrophic utilization of organic compounds are greatly influenced by the trace but highly dynamic pool of labile organic substrates. Free amino acids and other growth factors such as vitamins occur in exceedingly low concentrations in sea water but may undergo rapid utilization and synthesis. Degraded hydrolytic products of proteins, carbohydrates and fatty acids generally occur in large quantities within the DOM (dissolved organic matter) pool. In spite of low concentrations, these organic compounds are of major functional and ecological significance for the metabolism of the ecosystem.
